

The Human Microbiome

A World Inside You

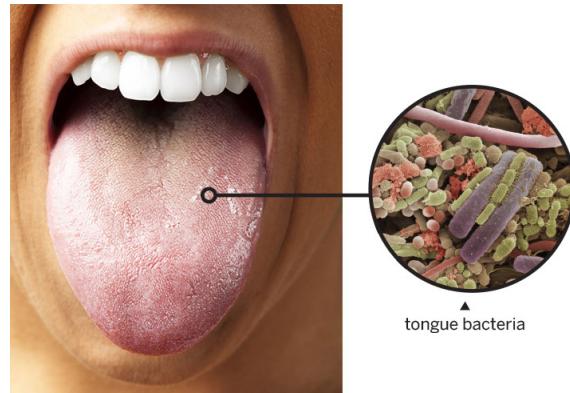

There's a world filled with strange creatures. The creatures of this world are invisible, and they're not human. Aliens sometimes threaten to invade the world these creatures call home. . . .

This world is not a far-off planet: it's your body! The creatures are called microorganisms, and your body is home to more than 100 trillion of them. Microorganisms live on your skin, in your gut, in your nose and mouth, and pretty much everywhere else on and in your body.

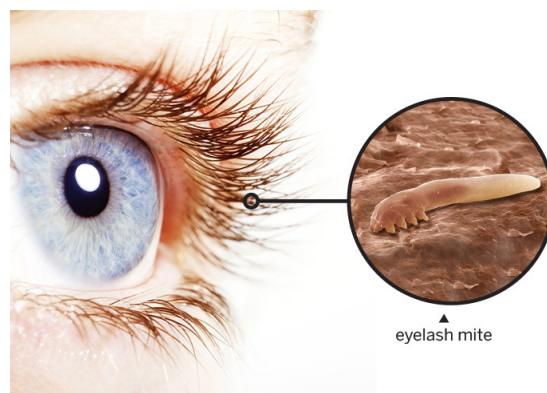

Your Body: Home Sweet Home for Bacteria

The microorganisms living in and on your body range from fungi to eyelash mites, but most of them are bacteria. Bacteria are among the smallest microorganisms on Earth. Most are made of a single cell—that's the tiny structure that makes up all living things. However, bacteria are not all the same. They come in different shapes, use different things as food, and live in different places. Thousands of different kinds of bacteria live in and on your body.

Even though they are tiny, bacteria are living things with the same basic needs that all living things share. The human body provides bacteria with the food and living space they need—that's what makes our bodies such a good environment for bacteria. One word for an environment and the organisms living there is *biome*, so we call the bacteria living in and on the human body “the human microbiome.” All together, the bacteria living in an average human's microbiome weigh

Your tongue is covered with bacteria like the ones in this photo, which was taken through a microscope. Bacteria are some of the smallest microorganisms that live in and on your body: these bacteria are actually 10,000 times smaller than they look in this photo! The bacteria colored green in this photo are 1 micrometer long, about 100 times too small to see with the naked eye. (The colors are not real: they were added to make the photo easier to see.)

This microscopic animal is an eyelash mite. It is harmless, and lives next to the roots of eyelashes. The photo was taken through a microscope, and shows the mite about 300 times larger than its actual size. This mite is about 210 micrometers in length. You might just barely be able to detect an eyelash mite with the naked eye in perfect conditions—if it weren't nearly transparent!

about 2 to 5 pounds. The number of bacteria in the microbiome of one human is millions of times greater than the number of people living on Earth!

Helpful Bacteria and Alien Invaders

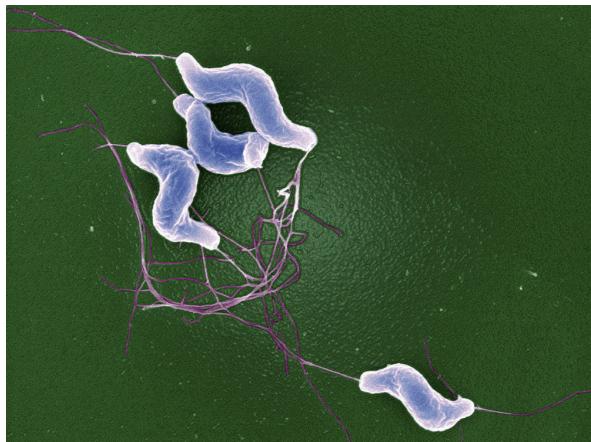

Most bacteria in the human microbiome won't hurt you. In fact, the opposite is true. Many bacteria do important jobs for the human body. For example, bacteria living in your gut help break down food that your body couldn't digest otherwise. Other bacteria help protect your body from infection, which helps to keep you healthy. All these helpful bacteria use the food and shelter your body provides. You depend on these bacteria, and they depend on you.

Unfortunately, not all bacteria are helpful. Harmful bacteria can invade the human microbiome through cuts, spoiled food, and even the air we breathe. An invasion of harmful bacteria or other microorganisms is called an infection, and infections can make people very sick. For example, a type of bacteria called *C. jejuni* produces a poison that harms cells from the human gut. When those cells can't function, the gut can't repair itself. This kind of *C. jejuni* infection can cause diarrhea, vomiting, and fever—all the symptoms of food poisoning.

Antibiotics and the Microbiome

Often, doctors treat infections with antibiotics. Antibiotics are medicines that kill bacteria. Antibiotics can stop dangerous infections, and they save millions of lives every year.

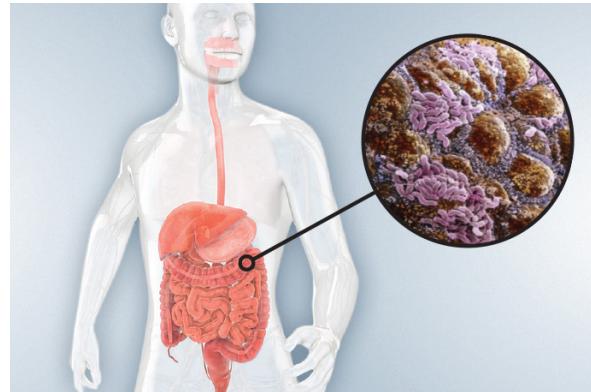

However, antibiotics don't just kill harmful bacteria—they kill helpful bacteria, too. A person who has just taken antibiotics has fewer bacteria than normal. Helpful bacteria will grow back in time, but often the bacteria that return are different from the ones that were there before. Taking antibiotics changes a person's microbiome.

What people call “food poisoning” isn’t caused by poisoned food: it’s usually an infection with harmful bacteria such as *C. jejuni*. (People added the colors in this photo to make the bacteria easier to see.)

Your Own Little World

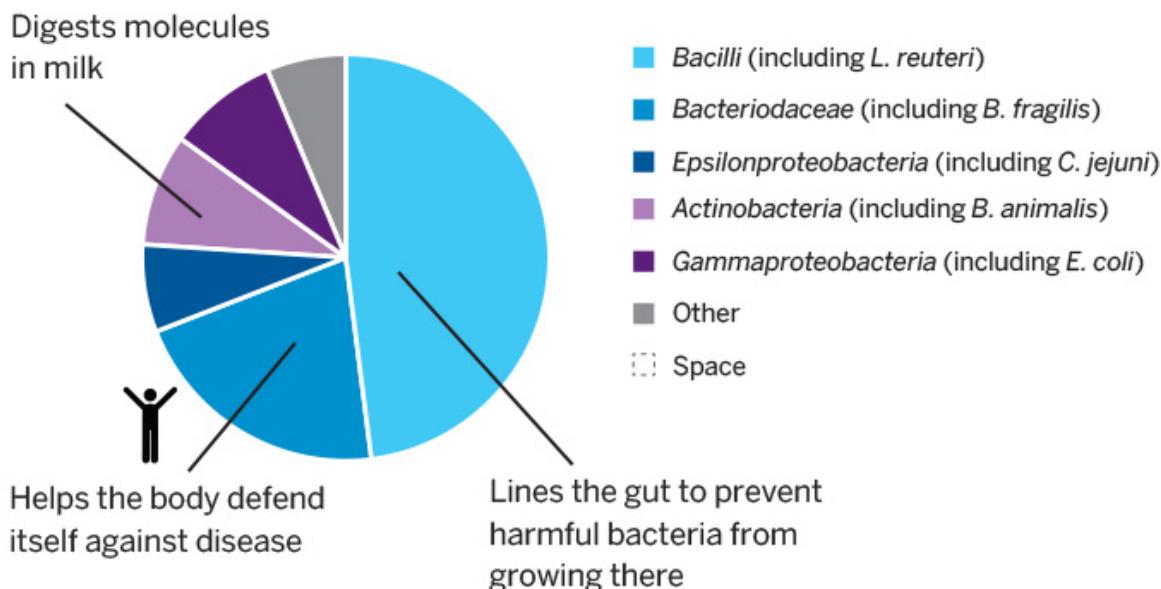

Your body is the whole world to the bacteria of your microbiome. It's an environment that provides microorganisms with everything they need, including food and space to live. What you do affects your bacteria, and they affect you, too. Your body is a world in miniature—a microbiome.

This microscope photo shows some bacteria in their natural environment: the human gut. The gut includes the intestines and stomach. In the photo, the bacteria appear 3,750 times larger than actual size. These bacteria are about 2 micrometers in length—nearly 50 times too small to see. (People added the colors in this photo to make the bacteria easier to see.)

Chart 1: Bacteria in a Healthy Gut Microbiome

Total number of bacteria: about 90 trillion

This pie chart compares the relative amounts of different kinds of bacteria in a typical healthy human's gut.

Meet a Scientist Who Studies the Human Microbiome

Dr. Susan Lynch is a scientist who studies ecosystems—not in the jungle or at the bottom of the ocean, but somewhere much, much closer: in the human body. Research shows that the body isn't just made of human cells—in fact, for every human cell in your body, there may be as many as ten cells belonging to bacteria and other microorganisms! Lynch studies those microorganisms, how they live together in the body, and how their interactions might cause people to get sick.

Some illnesses and medical conditions, like asthma, allergies, and some digestive problems, happen when the tissues of the body swell, or become inflamed. Inflammation is one of the body's ways of fighting off something that might be harmful, but it can also be dangerous. For example, during an asthma attack, the tissues of the airways swell up so much that air can't easily get through. The symptoms of allergies are also caused by inflammation: swelling inside the nose, around the eyes, in the skin, and in the airways. According to Lynch's research, some inflammation responses may be caused by the way many types of bacteria and fungi interact in the body, instead of by a single type of microorganism. Lynch says that microorganisms "don't live on their own. They live in communities, much like humans. They interact with one another and they interact with their environment."

Certain combinations of bacteria, fungi, and other microorganisms in the human microbiome can cause health problems, but other combinations may be able to keep people healthy. By identifying which combinations make people sick, scientists might be able to tell what changes to the microbiome could

Dr. Susan Lynch is a microbiologist who studies the human microbiome.

treat those illnesses or prevent them from happening at all. Someday, Lynch believes that doctors will be able to tell patients exactly what combinations of microorganisms they need in their systems to stay healthy.

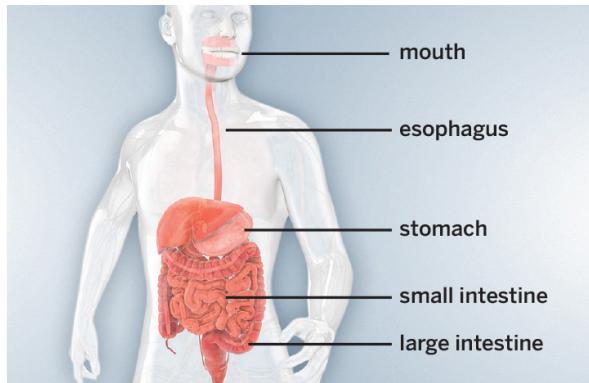

Growing up in a small town in Ireland, Lynch went to a tiny school. She always enjoyed science, and her high school biology teacher encouraged her to study microbiology in college. Lynch trained as a microbiologist, studying individual organisms and how they might cause illness. In 2005, she attended a talk in South America on the ways in which more than one microorganism can affect the body at the same time—and she decided to begin studying the whole human microbiome instead. "As soon as I knew about it, it just fascinated me—the idea of these organisms

that are incredibly powerful, and you can't see them, and they're everywhere," says Lynch. "And they dictate, in my book, pretty much everything that goes on on this planet."

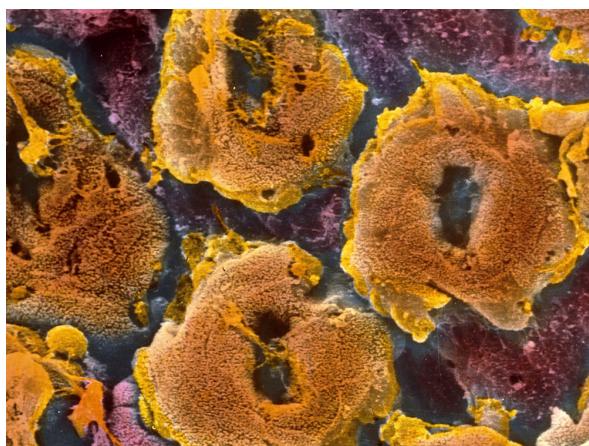

Today, at the University of California, San Francisco, Lynch works with many different types of scientists to study the human microbiome and how it affects the body as a system—which requires building bridges between different areas of science. To study the interactions between microorganisms and the body as a whole, scientists have to think and learn about topics outside of their usual areas of study. "In that way, we're kind of like our own little microbiome," she says. "Everybody brings different knowledge and skills to the table."

The study of the human microbiome is still in its early stages: scientists are trying to find out and describe the basics of how the microbiome works. Someday, scientists hope to understand exactly what happens during each interaction—and that could open up whole new fields of study.

Studying the human microbiome has its challenges, but Lynch says she loves learning new things—and she encourages young people to find something they love, too. "Go after something that you really enjoy, something that isn't a chore," she says. "I've ended up where I am because I've always gone after things that interest me. I eat, breathe, and sleep this stuff, and I love it."

Many of the microbes Dr. Susan Lynch studies are found in the human digestive system.

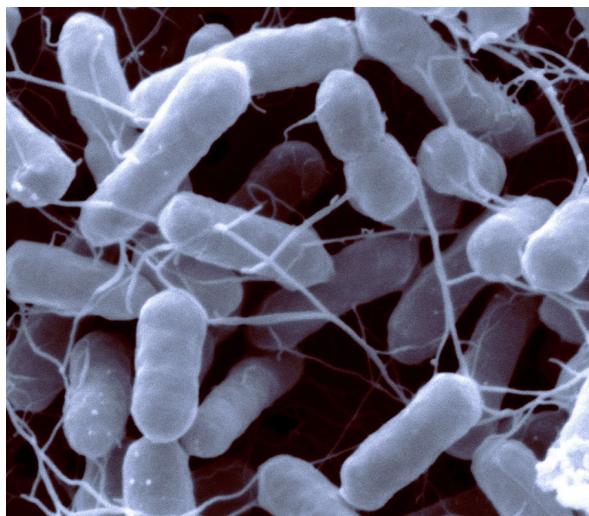

This photo, taken with a microscope, shows the wall of a gut infected with ulcerative colitis, a digestive problem that may be caused by the interaction between microorganisms. Lynch's work may someday help heal people with this condition. (Colors were added to the photo to make it easier to see.)

Bacteria: *Salmonella*

Food poisoning isn't caused by poison at all. Instead, what we call "food poisoning" is usually caused by bacteria, including *Salmonella*, a type of bacteria commonly found in chickens and other animals. *Salmonella* finds its way into our food and water and causes thousands of cases of food poisoning every year.

Environment

Salmonella lives in the guts of all kinds of animals, especially birds and reptiles, and usually gets passed around through animal waste. Whether a person gets sick from ingesting certain kinds of *Salmonella* can depend on the amount of food and space available in his or her gut microbiome. If the gut is home to lots of beneficial bacteria, the

Salmonella bacteria can cause the illness that people call "food poisoning."

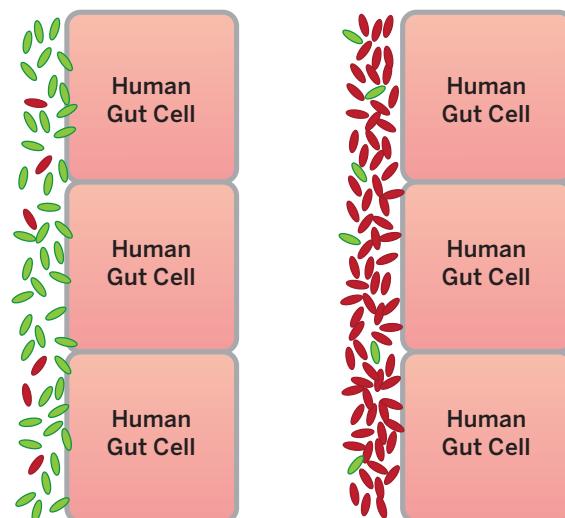

Salmonella bacteria can't get enough food and space to reproduce. On the other hand, if there are not many beneficial bacteria in the gut, the *Salmonella* population can grow and take over, causing illness—which in this case is more commonly known as food poisoning. *Salmonella* can be killed using heat, so cooking food properly is one way to keep from becoming sick.

Normal Role in Humans

Salmonella can sometimes be found in small amounts in the guts of healthy humans, but is more likely to be found in the microbiomes of people who have recently become sick from *Salmonella* infection.

Role in Disease

In most cases, *Salmonella* causes vomiting, diarrhea, and intestinal pain for up to a week. Most people get better without treatment from a doctor, but in severe cases, *Salmonella* can leave the intestines and move into the blood, where it causes severe disease and even death.

When lots of helpful bacteria (shown here in green) are present in the gut, there is little space and food available to harmful bacteria like *Salmonella* (shown here in red). This helps prevent the harmful bacteria from infecting the gut. When there are fewer helpful bacteria in the gut, there is more space and food available for harmful bacteria that can cause disease.

Bacteria: *C. difficile*

When scientists first discovered *C. difficile* (cee-diff-uh-SEEL), they named these bacteria difficile (which means “difficult”) because the bacteria were so hard to grow in the lab. Today, *C. difficile* might be considered difficult in another way: it causes hard-to-treat gut infections that kill thousands of people every year. Because it causes potentially deadly infections, *C. difficile* is sometimes referred to as “killer bacteria.”

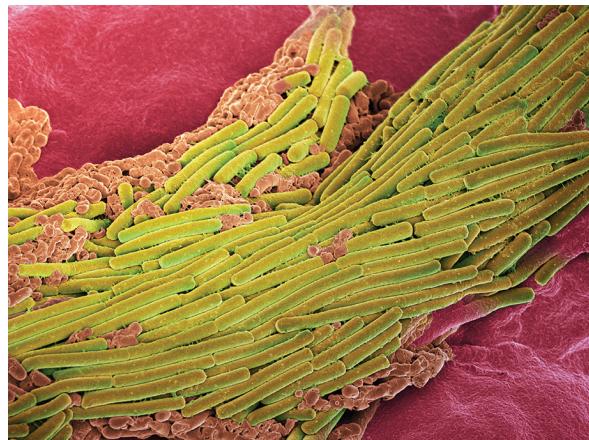

Environment

Although difficult to grow in a lab, *C. difficile* bacteria are very common in nature. These microorganisms are especially numerous in soil, where they use nearly anything as food. They can also survive in the environment of the human gut.

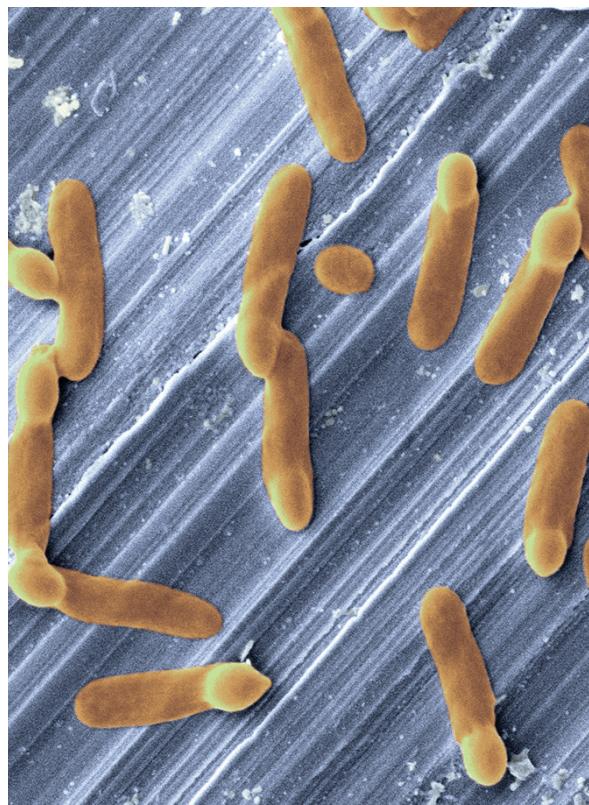

C. difficile has a surprising weakness: oxygen can kill it. However, it also has an amazing defense. When *C. difficile* is exposed to oxygen in the air or other dangers, it shrinks and forms a tough outer covering. In this state, *C. difficile* can survive oxygen, hand cleaners, acids, and even many antibiotics. Once the danger passes, the bacteria return to normal and begin multiplying.

Normal Role in Humans

Most healthy people do not have any *C. difficile* bacteria in their microbiomes. Even if someone accidentally swallows some *C. difficile* bacteria, the other bacteria in the gut keep the number of *C. difficile* low, and therefore safe. *C. difficile* cannot survive when there is a lot of competition from other bacteria for food and space.

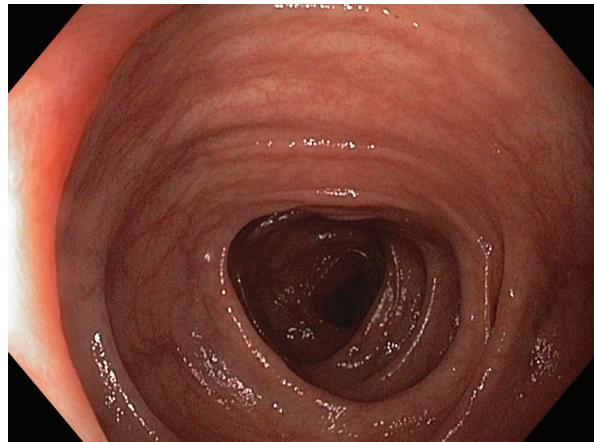

C. difficile bacteria can cause dangerous infections in humans. They are between 1 and 4 micrometers long. (This photo was taken in black and white; colors were added to make it easier to see.)

Exposed to the air on a steel surface, these *C. difficile* bacteria are shrinking and forming protective coverings. (This photo is zoomed in much closer than the previous photo.)

Role in Disease

When sick people take antibiotics, helpful microorganisms in the gut are killed along with the harmful ones. With the helpful gut microorganisms out of the way, *C. difficile* can multiply rapidly and take over the gut microbiome. The growing population of *C. difficile* produces powerful poisons, which irritate the cells of the gut lining and eventually cause the cells to die. *C. difficile* bacteria will then eat the dead cells—and may even escape through the damaged gut into the blood, spreading the infection. *C. difficile* infections can be very dangerous, and in some cases end in death. Bloating, diarrhea, and stomach pain are the most common symptoms. By causing constant irritation, *C. difficile* can make it harder for the immune system to function. Antibiotics can kill *C. difficile*, but until the person's normal microbiome is restored, the infection can come back.

This photo was taken inside a healthy human gut. The gut lining is smooth and healthy. (No bacteria are visible in the photo because they are too small to see in this view.)

This photo shows the gut of a human with a *C. difficile* infection. The gut lining is irritated and damaged. (No bacteria are visible in the photo because they are too small to see in this view.)

Bacteria: *B. fragilis*

Are *B. fragilis* (bee-fruh-JILL-us) bacteria beneficial to humans, or harmful? Without *B. fragilis*, people can have all sorts of health problems. However, these bacteria can also cause dangerous infections.

Environment

B. fragilis bacteria thrive in the environment of the human gut. In part, this is because *B. fragilis* has the ability to use nearly anything as food, including many substances that humans cannot break down. That means *B. fragilis* can take advantage of undigested food that flows through the gut. *B. fragilis* bacteria are also good at finding living space in the human gut: they stick themselves securely to the gut wall.

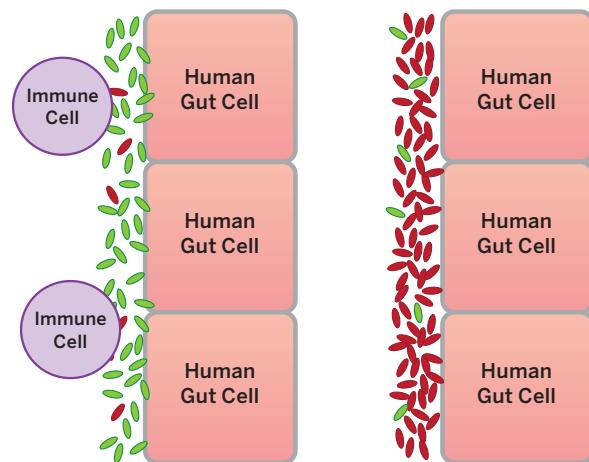

Normal Role in Humans

B. fragilis bacteria make up a small but important population in the healthy gut microbiome: usually about 0.5% of the bacteria in the human gut are *B. fragilis*. These bacteria normally help humans in several ways. First, they strengthen the body's defenses by helping the immune system produce enough immune cells to kill harmful invading bacteria.

Another important way *B. fragilis* bacteria help humans is through their habit of sticking to the gut wall. Because they take up living space, *B. fragilis* bacteria prevent harmful microorganisms from moving in. In addition, *B. fragilis* produces substances that help keep the cells of the gut healthy. Human gut cells need these substances to repair and protect themselves.

When they escape the gut, *B. fragilis* bacteria can cause dangerous infections. They use human cells as food! (People added the colors in this photo to make the bacteria easier to see.)

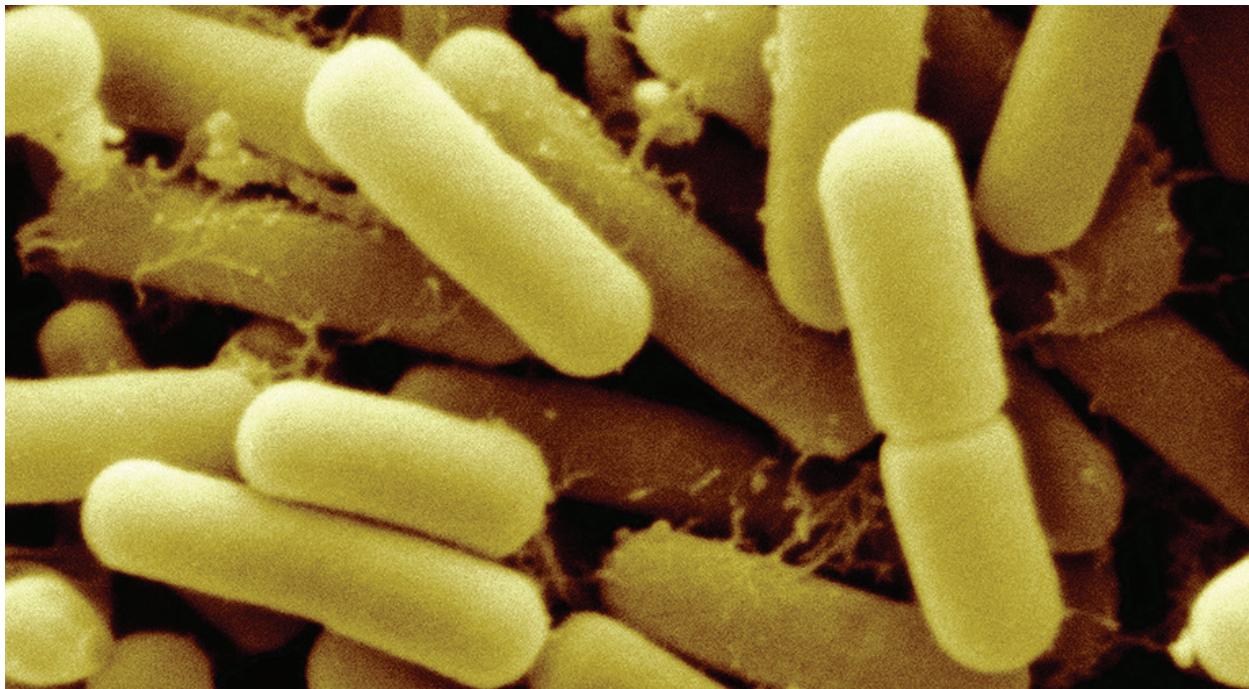

Bacteria like *B. fragilis* (shown here in green) help the body produce immune cells that kill harmful bacteria (shown here in red). When there are fewer of these helpful bacteria, there are fewer immune cells. This allows more harmful bacteria to live and cause infection.

Role in Disease

Even though they are usually helpful, *B. fragilis* bacteria can sometimes cause disease.

Often, this happens after the gut wall has been damaged in some way. As *B. fragilis* escapes from the gut, it becomes dangerous. *B. fragilis* does not usually hurt the cells in the gut because of the mucus that protects gut cells. Outside the gut, however, these bacteria can attack human cells and use them as food. Once they have infected the body outside the gut, *B. fragilis* bacteria are hard for the body's defenses to fight. To make matters worse, many antibiotics don't work well as treatments for *B. fragilis* infections.

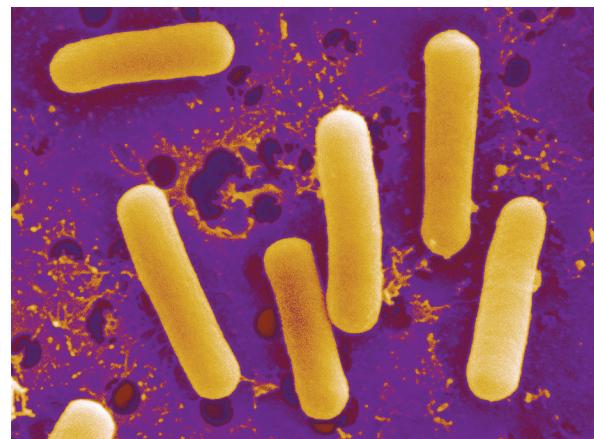

Large numbers of *L. reuteri* bacteria grow in sheets on the walls of the human gut.

Bacteria: *L. reuteri*

Many of the bacteria in our microbiomes help us, but *L. reuteri* (ell ROY-ter-eye) bacteria are some of the most helpful of all. In fact, some people take pills containing billions of *L. reuteri* bacteria to improve digestion. *L. reuteri* is one of the bacteria mothers pass to their babies through their milk. Having plenty of *L. reuteri* helps the babies have healthy gut microbiomes.

Environment

L. reuteri is found in the microbiomes of many animals, including most humans. These bacteria are extremely good at capturing food in the gut: they digest substances in food that humans are often unable to break down. They make a home for themselves by sticking to the gut wall. *L. reuteri* thrives in the gut environment, but it is rarely found living outside animals.

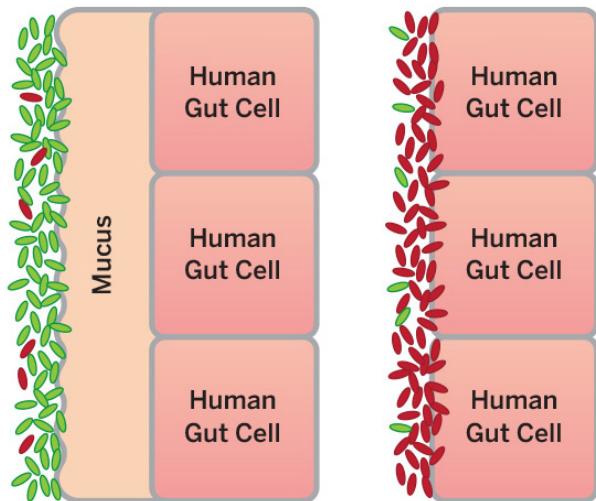

A helpful member of the gut microbiome, *L. reuteri* improves digestion and protects against infection. Each cell is between 2 and 4 micrometers long. (Colors were added to the photo to make the bacteria easier to see.)

Normal Role in Humans

L. reuteri bacteria help us digest food and produce vitamins that aid human health, but that isn't all they do. They also help protect humans from infection. *L. reuteri* helps the gut lining to produce mucus, which protects the gut and keeps it healthy. Large numbers of *L. reuteri* grow together in sheets stuck to the walls of the gut, preventing harmful bacteria from using that living space.

Role in Disease

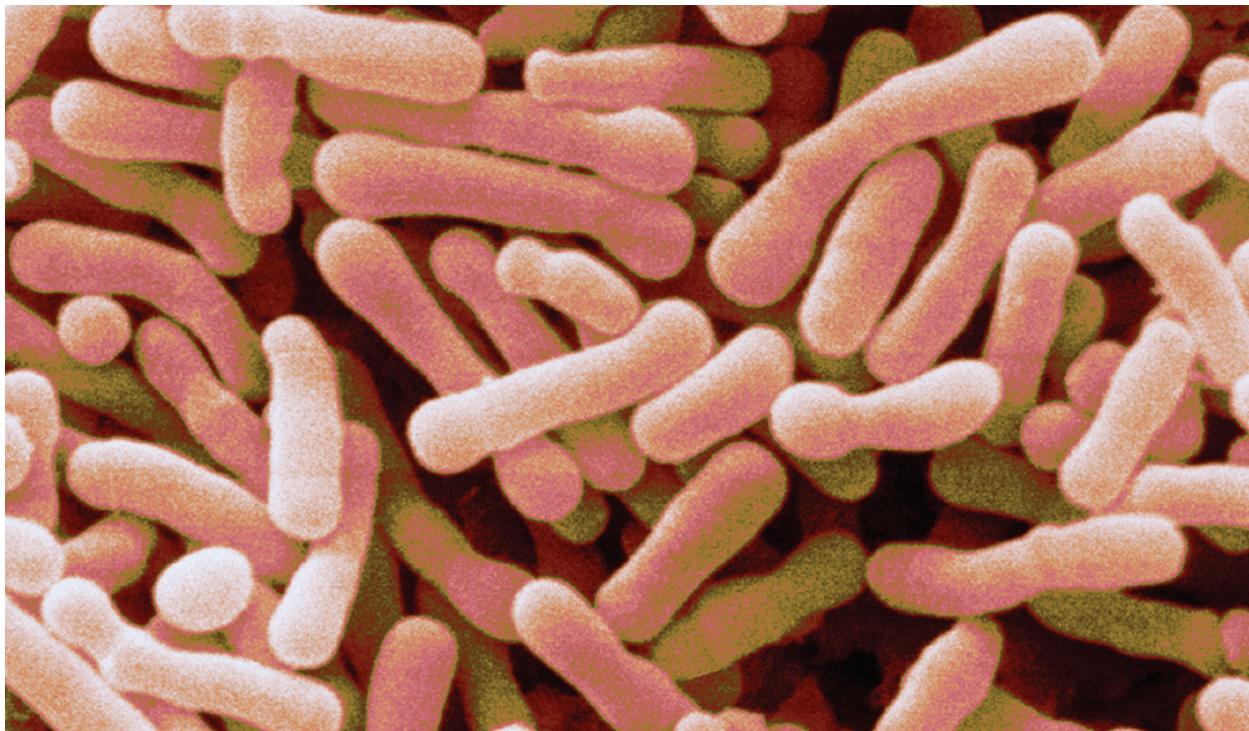

L. reuteri is not known to cause disease. In fact, it helps cure some diseases! Babies with gut infections that cause diarrhea, for example, will heal more quickly if given *L. reuteri* bacteria. The more scientists learn about *L. reuteri*, the more benefits they discover.

Some helpful bacteria, like *L. reuteri* (shown here in green), help the gut produce mucus that can protect gut cells from infection. When that mucus is not present, the human gut cells can more easily be infected by harmful bacteria (shown here in red).

Mothers pass *L. reuteri* bacteria to their newborn babies in their milk.

B. animalis is a helpful type of bacteria found in the human microbiome. Each one is 12 micrometers long.

Bacteria: *B. animalis*

You may have eaten a few billion *B. animalis* bacteria for breakfast this morning! *B. animalis* helps produce yogurt from milk, and a typical yogurt contains billions of these microorganisms. That's a good thing: *B. animalis* can be beneficial to human health. *B. animalis* is found in the guts of dogs, cows, mice, and nearly all other mammals, including humans.

Environment

B. animalis bacteria can be damaged by the oxygen in air. As a result, they thrive in low-oxygen environments like the human gut. There, they break down foods that humans cannot digest alone. Once in the gut, *B. animalis* competes fiercely for food and space, sometimes killing off harmful microorganisms.

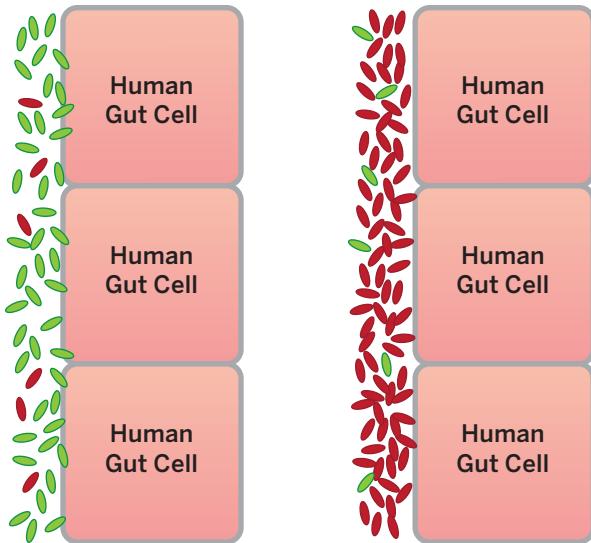

Yogurt often contains billions of *B. animalis* bacteria.

Normal Role in Humans

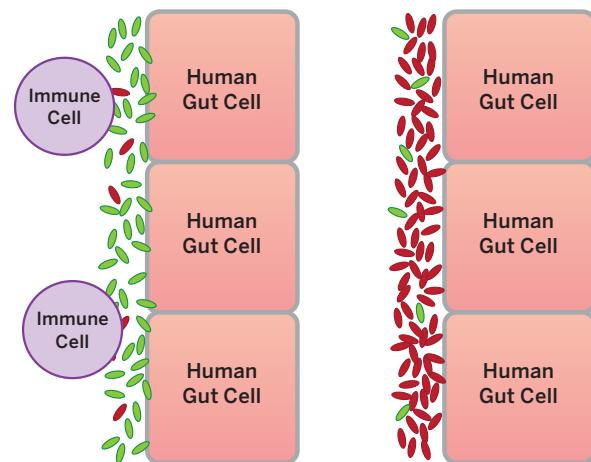

Bacteria like *B. animalis* are some of the first microorganisms to settle in our gut microbiomes—mothers pass them on to their newborn babies in their milk. *B. animalis* bacteria make up a relatively small part of the gut microbiome in adults. However, these bacteria still play a large role in keeping us healthy. As mentioned above, they compete fiercely with harmful bacteria for space and food. Competition from *B. animalis* helps prevent invading bacteria from increasing their populations. *B. animalis* aids in digestion and helps gut cells get the substances they need for repair and growth. It even boosts our immune systems, sending signals to our bodies to make more immune cells that can kill invading bacteria.

Role in Disease

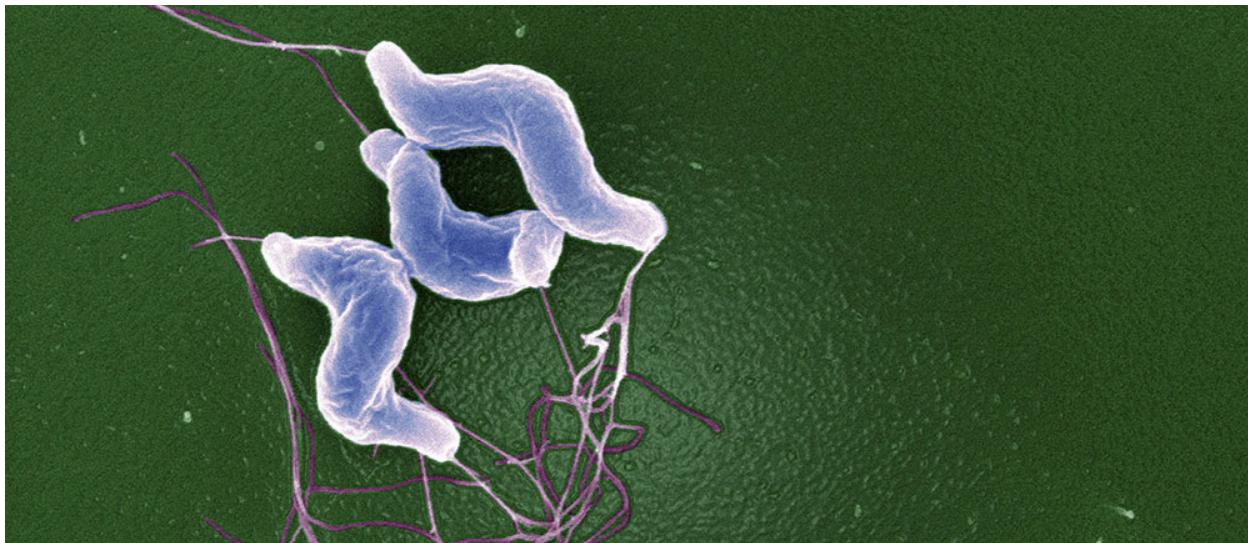

B. animalis bacteria do not cause disease when their population increases in the gut microbiome. In fact, not having enough *B. animalis* can cause problems! Low numbers of bacteria like *B. animalis* may be associated with some digestive problems, as well as problems with the immune system. Many people eat yogurt or take pills containing *B. animalis* bacteria to try to improve their health.

When lots of helpful bacteria like *B. animalis* (shown here in green) are present in the gut, there is little space and food available to harmful bacteria (shown here in red). This helps prevent the harmful bacteria from infecting the gut. When there are fewer helpful bacteria in the gut, there is more space and food available for harmful bacteria that can cause disease.

Bacteria like *B. animalis* (shown here in green) help the body produce immune cells that kill harmful bacteria. When there are fewer of these helpful bacteria, there are fewer immune cells. This allows more harmful bacteria (shown here in red) to live and cause infection.

This photo shows a few *C. jejuni* bacteria together in a group. Infections with *C. jejuni* cause what is known as food poisoning. (Colors were added to the photo to make the bacteria easier to see.)

Bacteria: *C. jejuni*

Have you ever heard people say they got “food poisoning”? What made them sick was probably *C. jejuni* (see-jeh-JUNE-ee) bacteria. *C. jejuni* bacteria are part of the normal microbiome in birds and cattle, but in humans, these bacteria cause more cases of food poisoning than almost any other microorganism! They are only 4 to 6 micrometers long, but *C. jejuni* bacteria can cause serious trouble.

Environment

C. jejuni bacteria can meet all their needs in the human gut, even though they don’t ordinarily live in this environment. Unlike helpful gut bacteria, these harmful bacteria don’t use our undigested food--instead, they steal from human gut cells. Using their corkscrew shape and two whiplike tails, *C. jejuni* bacteria make their way to the cells of the gut. *C. jejuni* will either grab nutrients from digested food before our cells get them, or invade the gut cells and eat what’s inside.

Normal Role in Humans

C. jejuni bacteria are not normally found in humans. In fact, these microorganisms do not benefit humans at all—but they seem to play an important role in the microbiomes of chickens, and many humans enjoy eating chicken. As you might expect, most people who get *C. jejuni* infections get them from chickens, often from eating undercooked meat.

Role in Disease

Once *C. jejuni* bacteria get into humans, they cause diarrhea, vomiting, and fever—all the symptoms of food poisoning. These symptoms result from a toxin that *C. jejuni* produces. The toxin harms gut cells, blocking them from repairing the gut. It also shuts down the body’s defenses. Even though *Salmonella* bacteria is more famous for causing food poisoning, *C. jejuni* is actually responsible for many more infections in the U.S. each year!

Some *C. jejuni* infections clear up in a few days, but others become severe and must be treated with antibiotics. Antibiotics quickly kill the *C. jejuni* invaders, along with most of the other microorganisms in the gut.

Bacteria: *E. coli*

The bacteria called *E. coli* (ee-COLE-eye) have a bad reputation. Most people know about *E. coli* only as harmful bacteria that cause disease and even death. However, there are actually many types of *E. coli*, and most of them play helpful roles in the human microbiome.

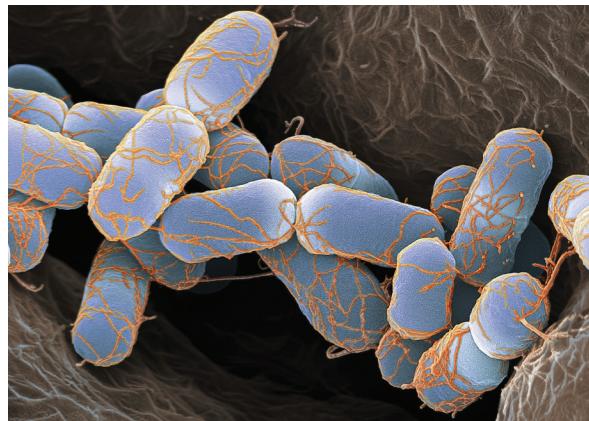

Environment

E. coli bacteria thrive in the guts of humans and other mammals. They grow best at temperatures near 37°C (98.6°F)—the same temperature as our bodies! *E. coli* can use many substances for food, nearly all of which are found in the gut. Unlike many gut bacteria, however, *E. coli* can also survive outside the body.

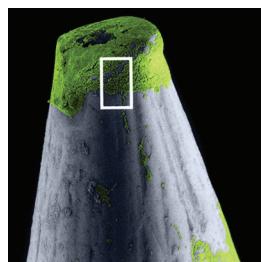

Normal Role in Humans

Healthy humans ordinarily have *E. coli* living in their microbiomes. Because *E. coli* bacteria are good at getting food and living space from the human gut, they multiply quickly when other microorganisms are reduced. In the right conditions, *E. coli* can multiply very fast: a population of *E. coli* bacteria can double in numbers every 20 minutes! *E. coli* benefits humans by taking up food and space that harmful invading microorganisms might use otherwise. Competition from *E. coli* helps prevent invading microorganisms from growing out of control.

Humans aren't able to digest every part of our food. It's the parts humans can't digest that *E. coli* uses for food. As the *E. coli* bacteria break down this undigested food, they produce vitamin K, a substance that boosts bone growth and helps form scabs to stop bleeding. *E. coli* also causes the gut to produce protective mucus.

This image of *E. coli* bacteria was taken through a powerful microscope. In the photo, the bacteria appear about 15,000 times larger than their actual size of just 2 micrometers! (*E. coli* isn't really blue; color was added to the photo to make the bacteria easier to see.)

The photo at left is a close-up of the sharp tip of a pin, covered with *E. coli* bacteria. The photo at right zooms in even further to show the individual bacteria 3,500 times larger than actual size. (*E. coli* isn't really green; color was added to the photo to make the bacteria easier to see.)

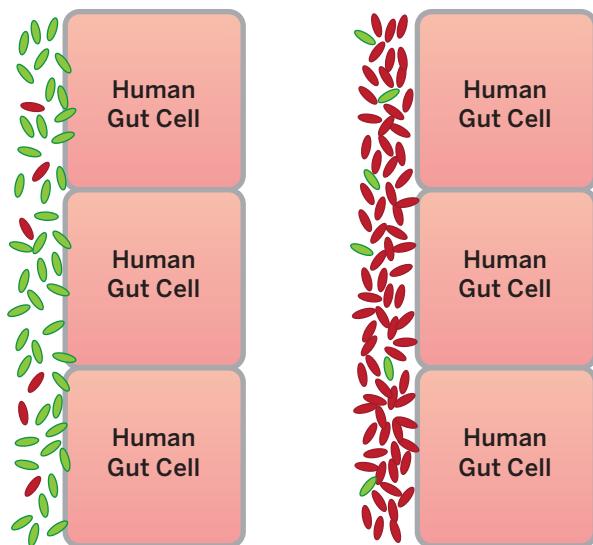

E. coli can multiply very quickly under the right conditions. (These bacteria aren't really pink; color was added to the photo to make them easier to see.)

These bacteria stay in our bodies throughout our lives. In fact, within 40 hours of birth, *E. coli* have moved in and multiplied in a newborn baby's gut. It's good that they move so quickly—otherwise, harmful microorganisms could move into a baby's gut without competition, and that could cause the baby to become very sick.

Role in Disease

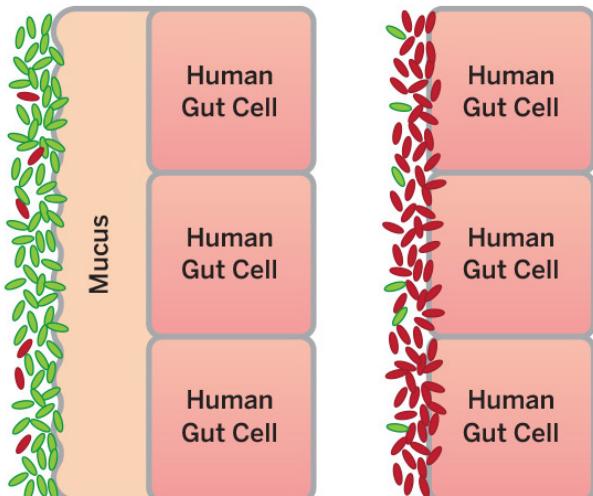

Even though most types of *E. coli* are beneficial, the harmful types are better known. These *E. coli* bacteria are dangerous. Because *E. coli* can survive outside the gut, harmful *E. coli* bacteria sometimes find their way into the food people eat. Infections with harmful *E. coli* cause "food poisoning," with severe vomiting and diarrhea. Some of these harmful types of *E. coli* actually turn the safe *E. coli* present in the microbiome into harmful *E. coli*! It's no wonder *E. coli* has a bad reputation. Still, the majority of *E. coli* bacteria are helpful, not harmful.

When lots of helpful bacteria like *E. coli* (shown here in green) are present in the gut, there is little space and food available to harmful bacteria (shown here in red). This helps prevent the harmful bacteria from infecting the gut. When there are fewer helpful bacteria in the gut, there is more space and food available for harmful bacteria that could cause disease.

This piece of lettuce has *E. coli* bacteria on it, viewed through a microscope and shown more than 5,000 times larger than actual size. People can become very sick if they eat food contaminated with harmful types of *E. coli*. (The photo was taken in black and white; colors were added to make it easier to see.)

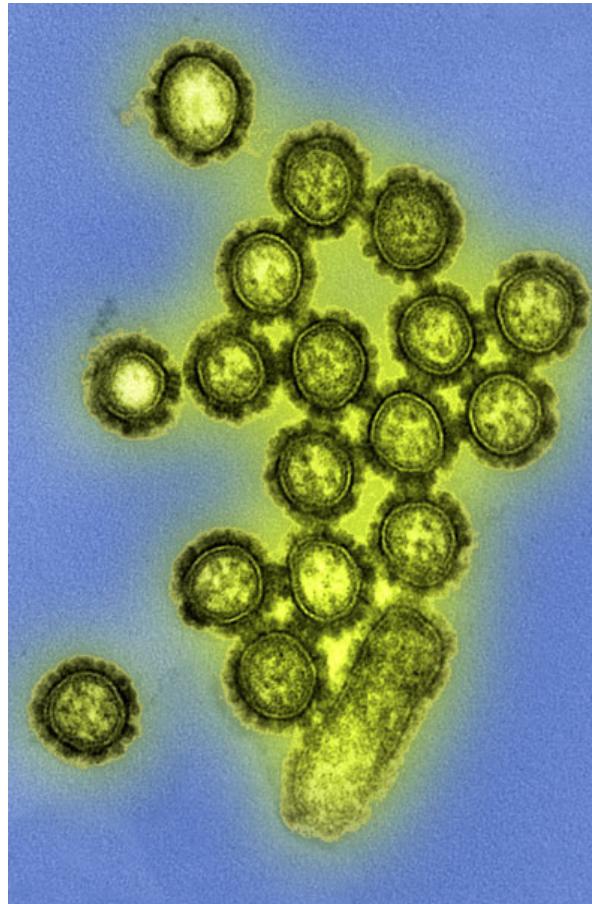

Some helpful bacteria, like *E. coli* (shown here in green), help the gut produce mucus that can protect gut cells from infection. When that mucus is not present, the gut cells can more easily be infected by harmful bacteria (shown here in red).

Viruses: On the Edge of Life

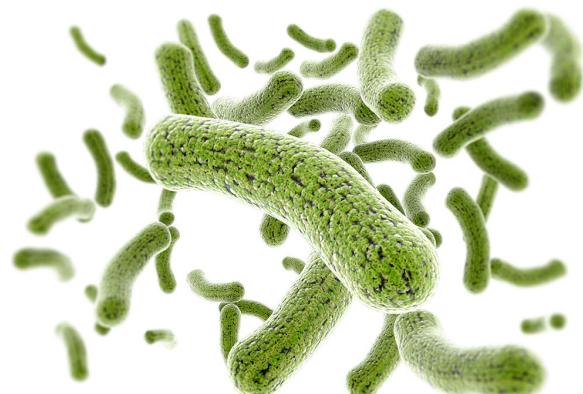

Oh, no: imagine you woke up this morning with a sore throat, an achy body, and skin that feels like it's burning up. You might have influenza, also known as the flu. Influenza is caused by a virus—a tiny structure that infects the living cells of animals, plants, and all kinds of bacteria and microorganisms. Viruses are one of the leading causes of illness in the world.

Viruses are very simple, and they exist on a microscopic scale: they're just tiny bundles of DNA covered in a coat of protein, sometimes with a layer of fat molecules for extra protection, and most of them are about 100 times smaller than the average cell—the largest are about 300 nanometers. Because viruses are so simple, scientists argue about whether they count as living organisms. On one hand, viruses aren't made of cells, which scientists consider the basic unit of life.

On the other hand, they have DNA and are able to reproduce, and they evolve through natural selection—all of which are important qualities of living things. Some scientists say that viruses are “on the edge of life.” Viruses may be simple, but they’re good at what they do: reproducing. Because viruses don’t have cell bodies of their own, they use the living cells of host organisms in order to reproduce. When it’s time to reproduce, the virus latches onto a living cell and injects its own DNA into the body of the cell. The virus’s DNA takes over the cell and forces it to make more viruses. When the host cell is full of new viruses, they burst out, killing the cell. Each new virus then looks for a new cell to infect, and the cycle begins again. For some viruses, this happens quickly—but some viruses hide their DNA in the host’s cells for years, allowing the cells to copy the virus’s DNA over

Viruses are tiny biological structures that cause illness in plants, animals, and all kinds of bacteria and microorganisms. (Colors were added to the photo to make it easier to see.)

Viruses share some characteristics with living things, but not all. Some scientists say they’re “on the edge of life.”

and over as the cells reproduce, but not actually making the host sick. For example, people infected with HIV can have the virus in their cells for years before they develop AIDS, which is a collection of serious symptoms caused by the virus.

Because they infect living cells, viruses are hard to treat without killing the host cells as well. The antibiotic medicines used to treat bacterial infections kill bacteria, but antibiotics don't have an effect on viruses. The best way to fight viruses is to prevent them with vaccines. A vaccine is a weakened version of a virus, which can be injected into a healthy patient. The weakened virus doesn't make the patient sick, but it does prepare the patient's immune system to fight the virus in the future.

Viruses are tiny bundles of DNA covered by layers of protein. (Colors were added to the photo to make it easier to see.)
